I

ACKNOWLEDGEMENT

This summary is based upon data collected by the various State water pollution control agencies, processed through the regional and headquarters offices of the Federal Water Quality Administration and published in detail in the 1968 Inventory of Municipal Waste Facilities. Appreciation is expressed to personnel of the State agencies for their collection efforts and to the staffs of the Federal Water Quality Administration's Regional Offices for their review, evaluation, assembly and submission of the data.

To the personnel of the Data and Information Services Section who faithfully and painstakingly edited, coded and prepared the data for publication, and to those of the Data Operations and Services Section who established the computer records of the inventory, grateful acknowledgement is also extended.

Computer production of all tables of 1968 data was made possible through the programming efforts of Mrs. Joyce Boyd, Computer Programmer.

INTRODUCTION

This publication presents a summary and analysis of data on sewage disposal and treatment facilities in the United States and territories. Detailed information on individual facilities will be published in the 1968 Inventory of Municipal Waste Facilities (1). The data reflect the status, characteristics and types of disposal and treatment facilities in place on January 1, 1968. The inventory is the fifth to be taken on a national basis. The previous four, in 1940 (2), 1945 (3), 1957 (4) and 1962 (5), were conducted and published by the Public Health Service.

Certain data from the statistical summaries of the previous inventories have been included in this publication to allow comparison with the 1968 inventory and to provide a measure of progress in the control and disposal of municipal wastes. Analyses of the data and of trends in the methods of collection, treatment and disposal of the wastes are included in the text.

BASIC DATA

General

The data summarized herein were collected between *January 1, 1968* and *July 14, 1969*, but are intended to reflect municipal sewage collection, treatment and disposal facilities existing as of January 1, 1968, together with any additional abatement needs. Flow rates and effluent data are supposed to show averages for the year 1967. Great care and effort have been expended to make the data as accurate and complete as possible; however, the user is cautioned to exercise judgement in making comparisons with earlier data. Shortages of manpower or other resources in some of the State agencies restricted to varying extents the effort which could be devoted to this project; hence, the differences between this and the 1962 inventory may not present a totally accurate picture of progress over the six year period. This could be especially true for the States of Pennsylvania, Florida and Tennessee for the results of final review by the States had not been received by the cut-off date for analysis and aggregation of the data.

It should be noted that some of the 1962 data included in this summary reflect correction of errors discovered after publication of the 1962 inventory.

All data are now stored on magnetic tape and as changes occur, errors detected, and new plants come into existence, this information can be changed or added to effect a perpetual inventory.

Definitions

For purposes of this summary, the key words "community" and "facility" are defined as follows:

A *community* is defined as any grouping of houses where there is a permanent resident population engaged in a normal domestic pattern of living. It is a named place to which a census or census-type population can be assigned. (Note: where a U.S. Census figure for 1960 was not available, data were taken from the 1961 Rand-McNally Atlas.) It may or may not be incorporated. It may or may not have its own disposal facility; or it may have more than one. In data tables relating to communities, the *number* of communities should be considered a minimum, because at least two States did not return all forms relating to communities which were served by some other disposal facility even though the populations served are properly reflected by the serving facility.

A *facility* is defined as a treatment plant or, in the case of raw discharge, the collection system. There may be more than one facility in a community or one facility may serve several communities. In the tabulations, the population served is associated with the serving facility only.

Grouping of Summary Data by Population and Drainage Basins

Population Size Groups

Each of the reports was placed in one of the 10 groups shown below according to the 1960 census population of the *community* in which the facility was located.

Group	*Population Range*
1	Under 500
2	500-1,000
3	1,000-5,000
4	5,000-10,000
5	10,000-25,000
6	25,000-50,000
7	50,000-100,000
8	100,000-250,000
9	250,000-500,000
0	500,000 and over

Facilities located in sanitary districts for which a census could not be determined were grouped according to the population served. Such a report is not counted as a community, but is counted as a facility. For example, Community A in Group 4 has 6,500 persons served by Community B in Group 7. Community A is counted as a community in Group 4, but the 6,500 persons served are counted in Group 7, where the serving facility is listed. Conversely, Facility B, located in Community B which falls in Group 3, serves 3,500 persons of Community B, but also 15,000 additional people in three other communities. The report is classified in Group 3, the size of the community in which it is located, but all 18,500 persons are counted in here as being served by the facility. The three other communities are counted as communities in their respective groups, but the population served is not counted. Thus, it is theoretically possible in a table for a count of a community to appear with no associated population served. It is also possible for a population served to appear with no community count, if the serving facility happens to be a sanitary district.

Drainage Basins

Following the Water Pollution Control Act of 1948, the Continental United States was divided into 15 major drainage basins as shown in Figure 1.

Alaska, Hawaii, Puerto Rico and the Virgin Islands have each been assigned arbitrarily as a major basin. The data in this publication have been summarized by these major basins only, although they have been tabulated by some 250 minor basins. These have been furnished to cooperating State agencies and are on file in the Washington office of FWQA. There has been one major change in major basin boundaries since the 1962 Statistical Summary which must be kept in mind if comparisons are made between the two periods. The Lower Hudson River—Metropolitan New York and the New Jersey Coast Minor basins have been shifted out of the North Atlantic Major Basin into the Northeast Major Basin.

Summary Data

The basic data in this summary are presented in Tables 1 through 9. Population served figures have not been rounded because of inherent difficulties in balancing between tables. However, *no fictitious precision is imputed to these data since they are, at best, only estimates.* Percentage tables, on the other hand, may not add because of rounding.

National summaries are given in Tables 1, 2, and 3 for sewer systems, sewage treatment and disposal. Details by States, population size groups, and major drainage basins are shown in Tables 5 through 9. The data in Tables 1, 2, and 3 are totals of later tables and are brought together for a quick summary of nationwide conditions.

Tables 2 and 3 are additive, as are the detailed tables from which they are taken. If more than one type of settling tank was present in a primary plant, the plant was classified as of the highest type. The general order was: Imhoff tanks; mechanically cleaned tanks; plain hopper-bottom tanks; settling tanks with no details; and, septic tanks. Similarly, when more than one secondary process was present, the classification was in this order: extended aeration; activated sludge; high rate trickling filters; standard rate filters; intermittent sand filters; stabilization ponds; and, application to land.

Data for selected intermediate and secondary treatment processes are given in Table 8. These are not additive, since a facility might use more than one. For instance, a trickling filter might be followed by a stabilization pond. In the plant classification, this would be considered as a trickling filter and counted once, but in Table 8, concerned with only the presence of processes, it is considered in both places and counted twice.

Table 4 shows the population served by the various population size groupings. This table is especially made to show the extent to which communities dispose of their wastes through the facilities of others. Populations served by another facility are counted throughout the tabulations with the serving facility. Table 4 shows there were over 30 million persons so served. For instance, there were 693,874 persons served by facilities in communities of less than 500 census population. In addition, there were 32,215 persons in places of this size group served by facilities of some other place of any size group. It happened that 1,835 were in the same size, under 500. Thus, it can be determined that in places under 500, there were 724,254 of the population connected to sewers, served by their own or other facilities. This

type of adjustment was not made on State or basin tables because a shift could occur only when persons in one State or basin were served by facilities in another State or basin. Hence, with these exceptions, the population served would be the same as the population connected to sewers.

II

DATA ANALYSIS

General

For January 1, 1968, the Census Bureau estimated there were 197 million civilian residents in the United States. From the data in this summary, 70 percent of the total population were connected to sewage systems for waterborne waste disposal. In 1962, the figure was 63 percent of the total population. Considering the increase in population, from 183 million to 197 million, or 8 percent, the rate of connecting the population to sewers, from 118 million to 140 million or 18 percent, is between 9 and 10 percent above the population growth. That is, in the six-year interval, sewage disposal construction has kept ahead of the population growth by that amount. There are 12,911 sewered communities in the 1968 inventory or 1,491 more than six years earlier. It is not known exactly how many of the nearly 13,000 are "new" in the sense that they have developed sewer systems since 1962, but it may be assumed that most, if not all, of the net increase fall into this category. This assumption is based on the fact that two States did not return all records for those communities served by some other facility, and there are other known consolidations or annexations which would have reduced the original 1962 figure had there been *no* new communities added. The reader is again reminded that numbers of communities where they appear should be considered minimum.

Of the 12,911 communities, 88.5 percent discharged treated sewage, 11.0 percent discharged all raw sewage and less than 1.0 percent discharged both treated and untreated sewage. Some type of treatment was provided for 93.2 percent of the total population connected to sewers. This figure is 5.6 percentage points above that for 1962. There was a total of 12,565 treatment plants, an increase of 31 percent over the last inventory. Of these, 79.8 percent were secondary and served 65.7 percent of the population receiving treatment. Table 21 shows that the number of secondary plants increased by 51.1 percent and the population served by this degree of treatment increased 40.0 percent since 1962.

States

Note: For convenience the word *States* in this summary includes the District of Columbia, Puerto Rico and the Virgin Islands—which are shown in alphabetical sequence.

Table 10 shows by States the percentage of the 1960 census of the sewered communities in the inventory which is connected to sewers and the percentages of the population served which discharge treated and untreated sewage. The percentage of the census population connected to sewers is not too meaningful because of the lapse of eight years reflecting population growth in the numerator and a theoretical no change in the denominator. Thus, all but 12 States show more than 100 percent of the census population connected to sewers—as much as 305 percent in Nevada. Of the 12 under 100 percent, eight showed some increase over 1962, but four did not—Massachusetts, Minnesota, Rhode Island and Vermont. For Massachusetts, a duplicate entry of 713,000 was found in the 1962 entry for minor treatment. Correction for this brings the 1962 percentage sewered down from 97.4 to 81.5. The 1968 figure is still two percentage points below the adjusted figure and the decline is attributed to loss of population in some of the industrial areas. (Minnesota reported for the first time some communities served by others which increased the total census population, but unfortunately, the serving facility populations were not increased to show proportionate changes in these figures. It is assumed the omissions in earlier inventories were oversights.) In addition, many new communities were added, with the total census population being indicated as served. Both these factors increased the census base, but the served population was not increased enough to show a percentage increase. Rhode Island's decline is attributed to losses of population served in the East Providence, Providence, and Newport areas which more than offset gains elsewhere. In Vermont many new communities were added, but only a fraction of the census population was connected to sewers at the time of the inventory.

In 34 States, more than 90 percent of the population connected to sewers were served by some kind of treatment—14 of these were 99 percent or better. Twelve others were between 50 and 90 percent, leaving five under 50 percent. The Virgin Islands was the only entry reporting no treatment. See Footnote 1 to Table 10 for explanation of lack of entries for Maryland and the District of Columbia.

Geographical Areas

Census Bureau geographical area grouping has been used in Table 11 to analyze general sewage work data. The States included in each group are listed in the footnotes, and have been arranged so that data can be compared with those of other fields pertinent to special problems analyses. As might be expected, the Middle Atlantic States have the largest population connected to sewers, followed by the East North Central Area. Continuing progress in sewage plant construction is indicated by the fact that in only three areas, New England, East South Central, and West South Central, does the percent of the sewer-connected population fall below 90 percent provided with treatment facilities. This indicates still further progress, considering that in 1962 seven of the 10 areas fell below 90 percent. Only in the combined noncontiguous areas of Alaska, Hawaii, and Puerto Rico, does the percent of the connected population receiving treatment fall below 70 percent.

Drainage Basins

Table 12 summarizes percentage data for sewer systems and raw and treated discharge by major drainage basins. There has been no significant change in community-totals distribution among the basins since the last inventory. The Upper Mississippi Basin, with 15.2 percent, has the largest percentage of communities, with the Ohio River Basin second with 12.2 percent. The continental basin with the smallest percentage of communities is the Great Basin with 1.1 percent. The Northeast Basin contains the greatest sewer-connected population (18.6 percent of the U.S. total), while Alaska, Hawaii, and Puerto Rico, with 0.9 percent of the communities combined, have the least population connected.

There are noticeable changes in the percent of connected population discharging treated and raw sewage as well as in the percent of total communities discharging treated and raw sewage. In every basin the percentage of connected population discharging treated sewage has increased in the last six years. The greatest change occurred in the Great Basin—23.9 percentage points. Of more importance, perhaps, was the 21.8 percentage point increase in the Missouri Basin because of the larger population involved—6.8 million compared to 1.3 million. In the Missouri Basin there was also a 7.7 percentage point increase in the proportion of communities discharging treated sewage, and a 4.2 percentage increase in the Great Basin.

The *Western Gulf*, with 5.9 percent of the U.S. sewered population, reported only one community out of 640 as discharging raw sewage. Contrastingly, considering the continental basins, the Southwest—Lower Mississippi River Basin had 79.2 percent of the connected population receiving treatment from 94.6 percent of the communities having such disposal facilities.

Population

For administrative reasons, population size groupings in this summary have been expanded from eight to 10 to break out the larger cities. Therefore, to make comparisons with earlier inventories the three highest groups need to be combined to read "100,000 and over". Table 13 brings together percentage distributions by population size groups relating to: (1) the number of communities; (2) the census population of those communities; (3) the population connected to sewers in the communities of the size shown without regard to the disposal means; (4) the population served by facilities in the group size shown without regard to the size group of those served; (5) the population served by raw discharge disposals in the size group shown; (6) the population served by treatment facilities located in the size group shown; and, (7) the number of those facilities.

Disposal facilities in communities of 100,000 or more served 52.9 percent of the population. This is 2.8 percentage points below that of six years ago. The relative decrease is reflected in the increase in number of communities and plants in the smaller categories, since 89 percent of the increase in number of communities is in the group under 5,000.

It will be noted that over half (51.8 percent) of the raw discharge is contributed by the three largest population groups. This is traceable to 27 of

the 1558 raw discharges. The 51.8 percent is 6.4 percentage points over the same figure for 1962, which also supports the indication of treatment plants being built in the smaller places. A decline of 4.2 percentage points in the proportion of treated sewage in these groups also supports the position.

Table 14 presents the percentage of census population connected to sewers and a percentage breakdown of that population discharging raw or treated waste for 1968. All size groups have sewered populations in excess of the census figure, with the total being 13 percent above the census. This mainly reflects growth since 1960 (the national growth was 11 percent), but part is due to connected populations outside the census-defined limits. The percentage of the population discharging raw sewage has reduced sharply over the last three inventories—22 percent in 1957, 12 percent in 1962, and now, just under seven percent. With complementary increases on the treated side of the ten population groups, only three have less than 90 percent treated—lowest being 88.1. Two groups are 95 percent or better, with the national average being 93.2 percent.

Comparison with Prior Data

Tables 15 through 19 bring together data that may be compared with earlier summaries beginning with 1940. In the past 28 years, the number of communities with sewers has increased from 8,500 to 12,900 (Table 15), although the latter number is a minimum for reasons previously stated. Sewered communities without treatment have dropped from a high of 3,800 in 1948 to 1,489 twenty years later. It is not known for certain, but a spot check of the data would indicate that probably as many as 400 of the 1,489 were brought into the inventory for the first time as being sewered since 1962. Some data revealed that treatment plants were under construction. The population discharging raw sewage was 28-30 million during the 1940 decade and now has dropped to less than 10 million. The treated sewage population on the other hand has more than tripled from 40 million to 131 million in the same time span. The percentage of the sewered population using treatment facilities increased 58 percent to 93 percent. Another measurement would be to relate the treated population to the total U.S. population. In 1940, less than one person in three was served by a treatment plant. In 1968, two persons of three were so served.

Stream Loadings

Table 16 shows the population equivalent of the Biological Oxygen Demand (BOD) load of waste water discharged to water courses. By relating the population equivalent of the sewage at the plant to the strength of the discharge it is possible to determine the percent reduction of BOD for each treatment type. These data were available for 13 percent of the plants serving 46 percent of the population connected to treatment facilities. The percentages so derived are shown in the first column. When applied to the total treated population, the net burden to the streams from plants could be determined. Added to this is the untreated sewage. The population so discharging was increased by 25 percent to show the population equivalent of this discharge. This increase is accounted for by industrial and trade

wastes. (Interestingly enough, this figure was between 30 and 37 percent for wastes going to plants.) The net load to streams is equal to the raw sewage of 54,323,000 persons. Despite the large increase in population, this is the lowest figure since data were available for 1940, and shows the effect of increased plant building and the emphasis on secondary treatment. Although there was a 42 percent increase since 1968 in the population utilizing secondary treatment, there was only a seven percent increase in secondary contribution to stream loadings. All other categories were down.

Development of Community Sewer Systems

In a book published in 1938, "Modern Sewage Disposal", C.G. Hyde (6) gave an interesting and comprehensive review of the development of sewage systems and treatment processes in the United States from the mid-19th century to the early 1930's. The data for 1860 through 1935 in Table 17 are adapted from that paper. With the inclusion of 1968 data, there is a 108-year record of the expansion in water-borne waste disposal. In every period except two, 1935-40 and 1945-48, the sewered population has increased faster than the national population. Since 1948 this rate has been nine, 10, and 11 percent greater than the census.

Since 1940 the census population has increased 50 percent while the sewered population has practically doubled. Between 1940 and 1949 the sewered population hovered between 53 and 54 percent. In 1957 the figure was 57 percent and in 1962, 65 percent. As of 1968, 70 percent of the population was connected to sewers. This percentage will go up in future years, but not reach 100 since it is estimated that there will be 50 million persons who for economic, engineering or geographic reasons are considered "nonsewerable".

Table 18 indicates that nearly three-fourths of the communities with sewers had census populations under 5,000 but these included only 11.5 percent of the total population connected to sewers. Increases in the relative percentages of communities in the lower population groups reflect the addition of the 1,490 places added to the inventory since 1962, and their contributions to the total populations. Cities of 100,000 or more make up less than one percent of the communities, but hold 43.0 percent of the persons involved.

Sanitary Districts and Communities Serving Others

Table 19 was developed from Table 4 and indicates the percent of the sewered population that was served by other than their own facilities and the percentage of the population served which was contributed by others. Table 4 shows that 30.3 million persons utilized these "other" facilities or 21.6 percent of the total connected population. The percentages have varied between 20.5 and 22.7 in the three inventories since 1957, but the number of persons has increased 51 percent over that time.

The percentages of both "served by" and "serving others" declined in all population groups under 10,000 again reflecting the construction of new plants since 1957. In fact, percentages declined in all population groups under 100,000 except that between 10,000 and 25,000 and this increase was

slight. For comparison, the groups of 100,000 and over combined were equal or almost unchanged since 1957. For 1968, the large cities over 500,000 had one person in five served by some other facility, however, nearly half (44 percent) of persons served by those cities were "outsiders".

Type of Sewers

Table 20 gives the percentage of communities having separate, combined, or both types of sewers within each of the population size groups. The national average is that 85.2 percent of the 12,111 communities which replied had separate sanitary and storm sewers. This figure is 2.7 percentage points higher than in 1962. All population size groups below 100,000 increased over six years earlier. The three largest groups when combined were down less than half a point. The extent of use of separate sewers varies inversely with the size of community. For places of less than 5,000 population, the percentage is 95.5 and decreases with each larger place group to 50.7 percent for those over 100,000. The reverse situation is true for combined sewers and for places that had both separate and combined types. These percentages now are 9.7 and 5.1 respectively.

Reference to Tables 1 and 5 will show that there was an increase of 1,000 in the number of communities using separate sewers, and no change in the number of communities using both separate and combined sewers. These tables also show that there was a decrease of 232 in the number of places reporting the use of combined sewers. At first glance, this might be taken as evidence of activity toward the physical separation of sanitary and storm wastes. Such a conclusion would be misleading. Between the two inventory periods of 1962 and 1968, this subject was questioned, the data were re-evaluated in the field offices, and as a result, many erroneous reports were corrected. It is possible that the current figure of 1,173 is still overstated. On the other hand, one must consider those communities for which the status was not given.

In 1962, 114 communities did not have a status given. In 1968, this number was 800. A detailed examination of each of these 800 showed that 570 were communities which were entered in the inventory for the first time. Of this latter number, 338 were in four States—Illinois, Michigan, Nebraska and Pennsylvania—and the remainder were scattered through 31 States. Eighteen States reported none. Significantly, all but 28 of the 570 communities were under 10,000 population. If it may be presumed that the 570 had sewers installed since 1962, it might further be assumed that in light of current policy and general practice, these new sewers in such sized places would fall into the "separate" category.

Treatment

Table 21 shows a comparison of the numbers of treatment plants and the populations served for the seven inventories since 1940 and the percentage relationship of 1968 to each of the earlier from 1945. Except for an increase of 10 in the minor treatment category, all plants of degree less than secondary have consistently declined since 1945. Secondary plants in 1968 were

more than 50 percent greater in number than 1962. While the number of primary plants have declined in number since 1949, the population served by them has increased each period. Populations served by secondary treatment, at 85.6 million, is 40 percent above 1962, double that of 1957 and nearly quadruple that of 1945.

Percentage distributions of treatment plants and populations served by size groups and drainage basins are given in Tables 22 and 23 respectively. There has been a continued accentuation in the shift in proportions from primary to secondary even though there was an absolute increase in populations served by primary in all groups. Considering the continental basins, the New England area had the highest relative proportion of plants in the primary category—48.0 percent—as well as the highest number—445. The second highest percentage was Western Great Lakes with 34.2 percent of the plants, but over half (51.7 percent) of the population is served by primary processes. The Pacific Northwest also showed half (50.5 percent) of its population as utilizing primary treatment. With 80 percent of the plants in the United States being of the secondary degree, and 66 percent of the population served, the lowest percentage of plants in this category was 49.0 in the Northeast followed by Western Great Lakes and Pacific Northwest. All percentages are more closely grouped around the national averages than in earlier years.

Primary Treatment

Table 21 shows the number of primary plants and the population served by them in the various types of processes. Altogether there were 2,384 such plants serving 36.9 million persons. Eight States, serving over one million each, accounted for 27.8 million or 70 percent of all persons connected to primary treatment. Of the 27.8 million, 22.2 million of these were in places of 100,000 population or greater. The most numerous type was mechanically cleaned tanks which displaced Imhoff tanks as the most common in 1957 and 1962. This type of treatment served 31.3 million persons or 85 percent of total primary.

Table 25 shows the percentage distribution by major drainage basins. The percentage of population served by Imhoff tanks is deceptively high in the Lake Erie, Western Gulf and Great Basins because the population bases are small, as Table 6 will show. In terms of numbers this method is popular in the Northeast, Southeast and Ohio River Basins.

Primary plants with mechanically cleaned tanks served 84.7 percent of the total population served by primary plants, with nine of the 15 continental basins showing individual percentages above this figure. The decline in proportion from 1962 shown for the Northeast Basin is brought about in part, at least, by a shift into the basin boundaries of the New York Metropolitan and Jersey Shores areas.

Intermediate and Secondary Treatment

There are 75 intermediate and 9,951 secondary plants in the United States serving 5.9 and 85.6 million persons respectively. Intermediate treatment is

defined as chemical treatment of sewage with sedimentation in the absence of any secondary process. The number of such plants declined from 85 in 1962 and the population served is down from 7.4 million.

In the secondary category, activated sludge plants went from 800 in 1962 to 1,309 in 1968, an increase of 64 percent, while the population served went from 33.3 million to 38.6 million or 16 percent. Of the 509 increase in number of plants, 346 or 68 percent were in places under 5,000 population. Extended aeration plants went from 154 in 1962 to 801 in 1968 with the population served rising from 409 thousand to 2.7 million. Standard rate trickling filters declined by 111 plants with a very slight increase in population while high rate filters increased by 393 plants with a 43 percent increase to 16.4 million.

Stabilization ponds as the principal means of secondary treatment numbered 3,457 in 1968, a 156 percent increase over the 1,347 in 1962. The population went from 2.2 million to 6.1 million in that period, almost threefold. While this type of treatment is more extensively used in smaller communities, some appear in all population size groups. Those in places over 25,000 are installations that serve subdivisions not connected to other plants. Table 26 presents a percentage distribution of plants and population served for population size groups. Table 27 presents the same information on distribution for major drainage basins.

With stabilization ponds being the most numerous type of secondary plants—one out of three—some geographical pattern might be expected. An examination of Table 27 shows that this type of plant dominates the Southeast Basin—and all the basins west of the Mississippi except the Great Basin, and there it is close. In none of the areas, however, does this type of treatment have the highest proportion of the population served. That characteristic goes to the activated sludge process in 10 of the 15 continental basins—all the basins east of the Mississippi except the Southeast, the Missouri, Colorado and California. The remaining five basins are dominated by trickling filters.

Table 28 compares usage of selected secondary processes with earlier inventories beginning in 1940. There was an increase in the number of all processes except standard rate trickling filters and intermittent sand filters. Stabilization ponds had the largest number, 3,837, which was more than double the 1962 figure, but the sharpest increase was extended aeration which, at 826, is more than five times the number six years ago. Populations served increased for all processes except standard rate filters.

Sludge Digestion

Units for the digestion of sludge were classified under four headings: septic tanks, Imhoff tanks, separate, and stage digestion (Table 9). Septic tanks were reported for 587 plants which is approximately 300 less than 1962. Imhoff tanks were reported 500 less than six years ago—2,364. Stage digestion increased from 630 to 754 while separate digestion went from 3,077 to 4,230, an increase of 37 percent.

Sludge Dewatering

Sludge drying beds were reported for 6,046 plants or about half the total 12,565 plants. Nearly 4,500 plants reported not having sludge dewatering or other organized drying methods. This number very nearly approximates the sum of septic tanks, Imhoff tanks and stabilization ponds as sewage treatment methods. A total of 191 reported use of sludge lagoons and 656 indicated mechanical devices were employed.

Chlorination

In 1968 there were 5,107 plants servicing almost 81 million persons, which had incorporated chlorination facilities (Table 9). This represents 40.6 percent of all plants and 61.9 percent of all persons served by treatment, and also a 48 and 47 percent increase respectively over 1962 in the number of plants and population. Pennsylvania had the largest number, but Alaska, Nebraska and the Virgin Islands reported none.

Grit Removal

Grit removal processes were reported in use by 3,343 plants serving 98 million people. This represents slightly more than one fourth of the plants but three-fourths of the persons connected to plants (Table 9). Table 29 shows that the percentage of plants removing grit increases as the size of the community; even so, the relative proportion of the plants using these devices in the large cities has declined since 1962.

Grease Removal

Grease removal was reported for 138 plants serving 12.1 million persons (Table 9). These figures represent only a slight increase over the 1962 figures of 113 plants serving 11.0 million people.

*Data are not available.
[1] 1940 census data.
[2] 1950 census data.
[3] Includes 166 communities discharging both raw and treated sewage.
[4] Includes 173 communities discharging both raw and treated sewage.
[5] Includes communities where only part of sewage is discharged untreated.
[6] Includes 100 communities discharging both raw and treated sewage.
[7] Includes 7,990 population discharging through semipublic facilities and not included in discharge data.
[8] 1960 census data.
[9] Includes 110 communities discharging both raw and treated sewage.
[10] Includes 73 communities discharging both raw and treated sewage.
